Abstract

Cysteine dioxygenase (CDO) is a mononuclear non-heme iron(II)-dependent enzyme critical for maintaining appropriate cysteine (Cys) and taurine levels in eukaryotic systems. Since CDO possesses both an unusual 3-His facial ligation sphere to the iron center and a rare Cys-Tyr crosslink near the active site, the mechanism by which it converts Cys and molecular oxygen to cysteine sulfinic acid is of broad interest. However, as of yet direct experimental support for any of the proposed mechanisms is still lacking. In this study, we have used NO as a substrate analogue for O₂ to prepare a species that mimics the geometric and electronic structures of an early reaction intermediate. The resultant unusual S=1/2 {FeNO}⁷ species was characterized by magnetic circular dichroism, electron paramagnetic resonance, and electronic absorption spectroscopies, as well as computational methods including density functional theory and semiempirical calculations. The NO adducts of Cys- and selenocysteine (Sec)-bound Fe(II)CDO exhibit virtually identical electronic properties; yet, CDO is unable to oxidize Sec. To explore the differences in reactivity between Cys- and Sec-bound CDO, the geometries and energies of viable O₂-bound intermediates were evaluated computationally, and it was found that a low-energy quintet-spin intermediate on the Cys reaction pathway adopts a different geometry for the Secbound adduct. The absence of a low-energy O₂ adduct for Sec-bound CDO is consistent with our experimental data and may explain why Sec does not act as a substrate for CDO.

Cysteine dioxygenase (CDO) is a non-heme Fe(II)-dependent dioxygenase that catalyzes the first step in oxidative cysteine catabolism, using both O atoms from molecular oxygen to convert L-cysteine (Cys) to cysteine sulfinic acid (CSA).^{1, 2} Cys is a necessary component in protein biosynthesis and also supplies the reactive thiol group for the synthesis of the biologically essential molecules coenzyme A and glutathione.^{3, 4} Elevated Cys levels have an excitotoxic effect on neurons, and an imbalance in Cys metabolism has been implicated in a variety of neurological diseases (e.g., Parkinson's, Alzheimer's, and motor neuron diseases) and autoimmune disorders (e.g., rheumatoid arthritis and systemic lupus erythematosus).^{5–9} Furthermore, the CDO product, CSA, is an important precursor in the biosynthesis of both taurine and pyruvate.³ Consequently, CDO plays a vital role in both producing important metabolites and maintaining appropriate Cys levels.

X-ray crystal structures of mammalian CDO have revealed that the active site of this enzyme features an Fe(II) ion ligated by three His residues and a solvent molecule arranged in a distorted tetrahedral coordination geometry. $^{10, 11}$ This facial 3His metal-binding motif, observed in only a few other enzymes to date, $^{12-14}$ is a fairly unique variation of the more common 2His1Carboxylate motif used by several other Fe(II)-dependent oxygenases. 12, 15–17 The active site of CDO also contains a rare covalent crosslink between the phenol ring of Tyr157 and the thiol group of Cys93. Although not itself a ligand to the Fe(II) ion, the second-sphere Tyr residue is close enough to potentially engage in H-bonding interactions with coordinated solvent molecules within the active site of the resting enzyme and/or with substrates during catalysis. A similar posttranslational modification has been observed in galactose oxidase (where it plays a vital part in catalysis)^{18, 19} and in NirA (where the function of the crosslink remains unknown).^{20–22} Hence it is not surprising that the C93-Y157 crosslink has been shown to be instrumental for catalytic activity in CDO, ²³ though its specific role during enzymatic turnover has yet to be established. Intriguingly, however, in prokaryotic forms of CDO, Cys93 is replaced by a Gly residue, and thus the Cys-Tyr crosslink is absent.²⁴ Despite this difference, the prokaryotic enzymes are still capable of oxidizing Cys at a rate similar to that of their mammalian CDO orthologs.²⁴

Following the publication of the X-ray crystal structures of both resting 10 and substratebound forms of CDO, 11 several different reaction mechanisms were proposed for this enzyme. 10, 11, 25–27 However, direct experimental evidence supporting any of these mechanisms is still lacking. Tight binding of the Fe(II) center to the 3His protein motif has been demonstrated through the use of Mossbauer spectroscopy. ²⁸ Crystallographic studies have revealed bidentate binding of the substrate Cys to the CDO active site through both its thiol and amino groups to yield a trigonal bipyramidal Fe(II) ligand environment. 11 Additionally, the ordered binding of substrates (Cys first, then O₂) and the formation of a 6coordinate, Cys- and O₂-bound Fe(II) center were proposed on the basis of an electron paramagnetic resonance (EPR) investigation of the NO adduct of Cys-bound Fe(II)CDO.²⁷ However, while several proposed mechanisms invoke subsequent electron transfer from the iron to the O₂ moiety, resulting in an iron(III)-superoxo type complex, the proposed mechanisms diverge widely after this point. One mechanism suggests the formation of a four-membered Fe(II)-S-O-O ring, with subsequent O-O bond scission and an oxidation state for iron that never exceeds +3.27 Alternatively, it was proposed elsewhere that an Fe(IV)-oxo species is generated during the transfer of the first oxygen to sulfur, after which a three-membered Fe(III)-S-O ring is formed to facilitate the transfer of the second oxygen to the sulfur. 11 A third, purely theoretical investigation by de Visser and coworkers led to the suggestion that the formation of an Fe(IV)-oxo complex is followed by a 'rebound' step, where the iron-sulfur bond is broken and an Fe-O-S linkage is formed. Transfer of the second oxygen to sulfur was then proposed to complete the reaction and restore the original Fe(II)-bound CDO resting state. ^{25, 26} Obviously, additional experimental work is needed to distinguish between any of these proposed catalytic mechanisms for CDO.

In a previous spectroscopic and computational study, we obtained detailed insight into the nature of the interaction between substrate Cys and the enzyme active site.²⁹ By utilizing NO to mimic the reactivity of Cys-bound Fe(II)CDO with O₂, a rather unusual species with an S=1/2 ground state was obtained,²⁷ as opposed to a coupled S=3/2 spin system (consisting of a high-spin Fe(III) coupled antiferromagnetically to NO⁻) that is typically observed for NO adducts of non-heme Fe(II) enzymes.³⁰ By using magnetic circular dichroism (MCD) spectroscopy, we subsequently determined that Cys binds to both Fe(II)-and Fe(III)CDO, and that the electronic transitions for the reduced and oxidized species are well separated in energy.²⁹ The substrate analogue selenocysteine (Sec) was also found to bind to both forms of CDO, as evidenced by the appearance of spectral features reminiscent of Cys-CDO, though red-shifted by 1,500–2,000 cm⁻¹. Additionally, resonance Raman

spectra obtained upon excitation into the S/Se \rightarrow Fe(III) charge transfer absorption bands were found to exhibit two features consistent with a direct Fe-S/Se bonding interaction. The MCD spectral signatures of Cys-Fe(II)CDO decayed when this putative reaction intermediate was exposed to oxygen, while those associated with Cys-Fe(III)CDO and all Sec-bound CDO species persisted, suggesting that only the Cys-Fe(II)CDO complex is catalytically active. Thus, although Cys and Sec bind in a similar fashion to the CDO active site, Sec cannot be oxidized by CDO despite the lower reduction potential of Sec vs. Cys at physiological pH (E°(Sec'/Sec $^-$) = +0.43V and E°(Cys'/CysH) = +0.92V vs. NHE). 29 , 31

In this study, we have utilized Cys and its substrate analogue Sec, in conjunction with the O_2 analogue NO, to mimic key steps in the reaction between O_2 and substrate-bound Fe(II)CDO. The resulting substrate (analogue)-bound species were characterized using a combination of electronic absorption (Abs), MCD, and EPR spectroscopic techniques along with density functional theory (DFT) and semi-empirical computational methods. Collectively, our spectroscopic and computational data provide new, experimentally supported insights into the CDO mechanism and afford clues as to why Sec is a competitive enzyme inhibitor rather than an alternative substrate for CDO.

Experimental Procedures

CDO Gene Expression and Protein Purification

The cdo gene from Mus musculus was expressed with an N-terminal maltose binding protein (MBP) tag in Escherichia coli BL21(DE3)RIPL cells. Cell growth and induction of gene expression using isopropyl β-D-1-thiogalactopyranoside (IPTG) were performed as described previously.²⁷ The harvested cell paste was resuspended in 25 mM HEPES (pH 7.5), treated with lysozyme for 30 minutes, and pulse sonicated on ice for 10 minutes to disrupt the cells. All subsequent steps in the isolation and purification of CDO were conducted at 4 ° C. This suspension was then centrifuged for 75 minutes at 39,200 ×g. To isolate CDO, the cell-free extract was diluted to a volume of 400 mL and applied to a preequilibrated diethylaminoethanol (DEAE) sepharose anion exchange column, which was then washed with two column volumes of buffer, followed by a linear gradient of 0 to 400 mM NaCl in HEPES buffer. Fractions containing the fusion protein were identified by sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) and further purified by loading them onto an amylose affinity column, to which the fusion protein selectively binds. After washing the non-binding proteins from the column, the target fusion protein was eluted in buffer (25 mM HEPES, 200 mM NaCl, 10 mM maltose, pH 7.5). The MBP tag was cleaved from CDO by incubating the solution containing the fusion protein with tobacco etch virus overnight at 4 °C. To remove the cleaved MBP, the protein solution was applied to an S-100 size exclusion column. Fractions containing CDO were identified by SDS-PAGE, pooled, and concentrated. As has been previously reported for CDO,³² our as-isolated protein consisted of two nearly equal fractions, one with and the other without the C93-Y157 crosslink being present (as revealed by the presence of a double-band pattern on an SDS-PAGE gel, see Figure S1). No efforts were undertaken to separate these two species or to change their relative populations.

Sample Preparation

Approximate protein concentrations were determined spectrophotometrically, using an ϵ_{280} value of 25,300 M⁻¹cm⁻¹ (note that the CDO concentration may have been slightly overestimated due to residual MBP in solution).²⁹ The Fe content was determined using a colorimetric assay with bathophenanthrolinedisulfonic acid as described previously,²⁷ and ranged from ~55–75% among all preparations. Samples used for spectroscopy were 2 mM in Fe-bound CDO. Degassed, as-isolated CDO was reduced under an N_2 atmosphere to

Fe(II)CDO by adding a slight molar excess of sodium dithionite, which led to a complete loss of color. Samples containing substrate (analogue) were prepared anaerobically and contained a 5-fold excess of Cys or Sec. Sec was prepared by anaerobic reduction of selenocystine with tris(2-carboxyethyl)phosphine. NO(g) was generated through the reaction of sodium nitrite with Cu(II) chloride and ascorbate under an argon atmosphere. He NO produced in this reaction was transferred via gas-tight syringe to the head-space of a small Ar-purged vial containing substrate (analogue)-bound Fe(II)CDO and allowed to react with the protein for up to an hour on ice. Sufficient NO gas was transferred such that additional gas did not result in a further change in color. All samples used for low-temperature (LT) Abs and MCD experiments also contained 55% (v/v) glycerol.

Spectroscopy

Room temperature (RT) Abs spectra were obtained using a Varian Cary 5e spectrophotometer while the sample compartment was purged with $N_2(g)$. LT Abs and MCD spectra were collected with a Jasco J-715 spectropolarimeter in conjunction with an Oxford Instruments SM4000-8T magnetocryostat. The MCD spectra presented herein were obtained by taking the difference between spectra obtained with the magnetic field aligned parallel and antiparallel to the light propagation axis to reduce contributions from the natural CD and glass strain. Iterative Gaussian deconvolutions of Abs and MCD spectra were conducted using Igor $6.22a.^{35}$

X-band EPR data were collected using a Bruker ESP 300E spectrometer equipped with a Varian EIP model 625A continuous wave frequency counter. The sample temperature was maintained at 20 K by an Oxford ESR 900 continuous flow liquid He cryostat that was regulated by an Oxford ITC4 temperature controller. Spectra were fit using the W95EPR program developed by Dr. F. Neese. 36

Computations

Quantum mechanics/molecular mechanics (QM/MM) calculations were performed with Gaussian 09. 37 For the QM region, density functional theory (DFT) was utilized in conjunction with Becke's three-parameter hybrid exchange functional with the Lee-Yang-Parr correlation functional (B3LYP), ^{38, 39} as well as the 6-31G basis set⁴⁰ for all atoms except iron, its immediately ligated atoms, and the NO or O₂ ligand, for which the TZVP basis set⁴¹ was used. For the MM portion of the calculations, the Amber95 force field⁴² was utilized. Residues R60, H86, H88, C93, H140, H155, and Y157 were placed in the OM region, as were the iron center, six crystallographically defined water molecules within 10 Å of the Fe atom, and all substrates and substrate analogues. For each of these protein residues, the QM/MM boundary was placed between the alpha and beta carbons, with hydrogen used as the link atom. The alpha carbons of these residues were frozen during the optimization process. As a crystal structure of mouse CDO with only Cys bound at the active site was unavailable at the time this work was initiated, we utilized two separate crystal structures in the generation of our starting coordinates, namely the 1.4 Å resolution crystal structure of persulfenate-bound CDO from rat (PDB file 3ELN⁴³) for all non-hydrogen atoms except those in the QM region, for which the 2.7 Å resolution structure of Cys-bound CDO from human (PDB file 2IC1¹¹) was used instead. All H atoms were added using the Reduce 3.14 program.⁴⁴ Based on an inspection of potential hydrogen bonding interactions, His residues were protonated at N_ε, except for H86, H88, H140, and H155, which were protonated at N_δ. For the NO adducts, the N and O atoms were manually added trans to H86 in a manner approximating a bent Fe-N-O net bonding interaction.

For comparative purposes, analogous QM/MM geometry optimizations were also carried out using an alternative functional (BP86 $^{45,\,46}$) and basis set (Slater's single valence polarized,

SV/C⁴¹). In the case of the Cys adduct of Fe(II)-CDO, these calculations predicted an S=0 ground state, rather than the S=2 ground state we observe experimentally and properly reproduce with the B3LYP functional. Also, while the computations with the BP86 functional correctly predicted an S=1/2 spin ground state for the NO/Cys-Fe(II)CDO complex, the resulting electron configuration for this $\{\text{FeNO}\}^7$ species (a low-spin Fe(III) coupled antiferromagnetically to NO⁻) is distinctly different from the configuration we determined experimentally (a low-spin Fe(II) ion coupled to an NO·) and obtained using the B3LYP functional. Especially in light of this latter observation, we opted to use the B3LYP functional in this work.

In the generation of small active site models from the QM/MM energy-minimized protein structures, iron, the substrates, H86, H88, and H140 were included. The protein residues were truncated at the alpha carbon and the immediate protein backbone atoms were substituted with hydrogens with a C-H bond distance of 1.1 Å. Spin-unrestricted singlepoint DFT calculations were performed on these active site models using the Orca 2.9 package developed by Dr. F. Neese, 47 with the same functional and basis sets that were utilized for the QM/MM computations (vide supra). Electronic transition energies and absorption intensities for the NO adduct of Cys-Fe(II)CDO were computed by utilizing the INDO/S-CI module as implemented in Orca 2.9. In this program, spin-orbit coupling was introduced by implementing an effective potential/mean-field approach for evaluating oneelectron terms and an exact calculation of the Coulomb potential. PyMOL version 1.5.0.4⁴⁸ was employed to generate isosurface plots of molecular orbitals (MOs) and electron density difference maps (EDDMs) using isodensity values of 0.06 au and 0.001 au, respectively. EPR parameters for the active site models were computed with Orca by solving the coupledperturbed self-consistent field (CP-SCF) equations ^{49, 50} using the B3LYP hybrid functional and the TZVP basis set on all atoms, except iron and the nitrogen of the NO ligand, for which CP(PPP)^{51, 52} and IGLO-III⁵³ were used, respectively. These calculations included all orbitals within a ±100 hartree window around the HOMO-LUMO gap, where the origin of the g tensor was defined as the center of electronic charge. A high-resolution radial grid with an integration accuracy of 7.0 was used for the Fe atom and the N atom of the NO ligand.

The coordinates from the QM/MM-optimized NO adducts of Cys- and Sec-Fe(II)CDO were used as a starting point for geometry optimizations of the corresponding O₂ adducts, where three viable multiplicities for the QM region were considered (singlet, triplet, and quintet). The oxygen adducts were further analyzed computationally by modifying their coordinates to approximate previously proposed reaction intermediates. The same QM/MM methodology described above for the NO adduct was then utilized to minimize the energies of complete protein models of these intermediates. The model energies obtained from a single-point calculation of small active site models derived from the QM/MM-optimized coordinates were drastically different from the SCF energies of the converged, whole-protein QM/MM models. In addition, the energetic ordering of the proposed O₂-bound species changed if only the contributions from the first coordination sphere were considered. Thus, the energies of all models reported herein are the SCF energies from the QM region of the QM/MM optimizations.

Results

Spectroscopy

The RT Abs and LT MCD spectra exhibited by the species obtained by adding first Cys and then NO to Fe(II)CDO are shown in Figure 2. The temperature-dependent MCD features observed at high energy (>28,000 cm⁻¹) are strikingly similar to those observed in the MCD spectrum of Cys-bound Fe(II)CDO in the absence of NO;²⁹ thus, we assign them as $S \rightarrow Fe(II)$ charge transfer (CT) transitions arising from a fraction of Cys-bound Fe(II)CDO

species that did not react with NO. However, additional temperature-dependent MCD features are observed in the lower-energy region ($<28,000~\text{cm}^{-1}$) of the MCD spectrum obtained in the presence of NO. The appearance of these features indicates that NO likely coordinates directly to the Fe(II) ion. This conclusion is corroborated by a previous EPR study, which revealed that the NO adduct of Cys-Fe(II)CDO is best described as a six-coordinate S = 1/2 FeNO⁷ species (utilizing the nomenclature of Enemark and Feltham, where the superscript denotes the sum of the Fe 3d and NO π^* electrons⁵⁴) consisting of an NO radical (S = 1/2) directly ligated to a low-spin (S = 0) Fe(II) ion.²⁷

The Abs and MCD spectra obtained for the NO adduct of Sec-bound Fe(II)CDO are also shown in Figure 2. As in the case of the Cys-bound NO adduct, several new MCD features are observed in the near-IR and visible spectral regions upon addition of NO to Sec-bound Fe(II)CDO, providing compelling evidence that NO also coordinates directly to the Fe(II) center in this species. The MCD features of NO-bound Sec-Fe(II)CDO are red-shifted between 200 and 2,400 cm⁻¹ from those of the Cys-bound analogue, which is reminiscent of the red-shifts displayed by the Abs and MCD features of the Sec- vs. Cys-bound Fe(II)CDO species in the absence of NO.²⁹ These shifts reflect the fact that the occupied frontier molecular orbitals (MOs) of Sec are higher in energy than those of Cys and are thus closer in energy to the Fe 3d-based unoccupied MOs.

The similar natures of the NO adducts of Sec-Fe(II)CDO and Cys-Fe(II)CDO are further highlighted by the similarity between the corresponding EPR spectra (Figure 3). In each case, a rhombic EPR spectrum is observed, with resolvable hyperfine coupling to an *I*=1 nucleus in the region of g₂. Fits of the experimental EPR data yielded the g values and hyperfine coupling constants listed in Table 1. Previously, the small spread in g values and the well-resolved hyperfine structure exhibited by the NO/Cys-Fe(II)CDO species were shown to be characteristic of a low-spin Fe(II) center coordinated to an NO:.²⁷ As anticipated on the basis of their similar EPR spectra, the NO adducts of Cys- and Sec-Fe(II)CDO display nearly identical g values and hyperfine coupling constants, indicating that the two species have very similar electronic, and thus likely geometric, structures.

Computations

To further characterize the NO adducts of Cys- and Sec-bound Fe(II)CDO, QM/MM geometry optimizations were performed on complete protein models. The corresponding active site structures were used in subsequent single-point DFT and semi-empirical calculations to allow for a direct comparison with the experimental data. In the QM/MM-optimized structures, the iron center adopts a distorted octahedral coordination environment, with the substrate cysteine coordinating in a bidentate fashion through both its thiol and amino groups, as observed in the X-ray crystal structure of Cys-bound CDO. The relevant bond distances and angles of the QM/MM-optimized active site models are in reasonable agreement with those determined by X-ray crystallography for the Cys-bound CDO crystal structure, as well as for synthetic S=1/2 {FeNO}⁷ complexes (see Table 2). 55–57

The EPR parameters computed for these active site models reproduce both the g spread and the magnitude of the ¹⁴N hyperfine coupling constant obtained from fits of our experimental spectra quite well. Although the actual g values are underestimated by the calculation, similar discrepancies are observed between the experimental and computed EPR parameters for synthetic, structurally characterized S=1/2 {FeNO}⁷ species (see Supporting Information, Table S1 for more details). While similar optimized geometries and computed EPR parameters were obtained with both functionals (B3LYP and BP86) and basis sets (6-31G/TZVP and SV/C/TZVP) we tested, the results of the INDO calculations described below exhibited much better agreement with experimental data when the B3LYP and

6-31G/TZVP QM/MM-optimized models were used (see Figure S2). Thus, B3LYP and 6-31G/TZVP were utilized for the remainder of the calculations.

The good agreement between the metric parameters of the QM/MM-optimized active site models of the NO adducts of Cys- and Sec-bound Fe(II)CDO and the relevant X-ray crystal structure data, as well as between the computationally predicted and experimentally determined EPR parameters, warrants a closer examination of the computational results. For the NO/Cys-bound Fe(II)CDO species, the optimized Fe-N(His86) and Fe-N(His88) bond lengths are identical (at 2.11 Å), while the Fe-N(His140) bond trans to the cysteine substrate amino group is slightly shorter (at 2.01 Å). Very similar Fe-N(His) bond lengths result for the analogous Sec-bound species. Consistent with Fe-Se bonds being inherently longer than Fe-S, the calculated Fe-Se(Sec) bond distance is 0.13 Å longer than the Fe-S(Cys) bond distance. In contrast, the Fe-N(O) and N-O bond lengths, as well as the Fe-N-O bond angle, are almost identical between the two species, further supporting the conclusion that the substitution of Sec for Cys does not significantly affect NO binding. The geometric parameters of the Fe-NO unit are also comparable to those of synthetic, crystallographically characterized S=1/2 {FeNO}⁷ complexes (see Table 2).⁵⁸, ⁵⁹

As anticipated from the experimental EPR spectrum of NO/Cys-bound Fe(II)CDO, the calculated molecular orbital (MO) diagram (Figure 4) is consistent with a pseudooctahedral, low-spin Fe(II) complex, with the Fe 3d_{xv}-, 3d_{vz}-, and 3d_{xz}-based occupied MOs considerably lower in energy than the Fe 3d_x2_{-v}2- and 3d_z2-based unoccupied MOs. The formally singly occupied MO corresponds to the second-highest occupied spin-up (a) MO (α -HOMO-1) because the corresponding spin down (β) MO (i.e., the β -LUMO) is unoccupied. The α-HOMO-1 has 72% NO and 19% Fe 3d character, making it weakly σbonding with respect to the Fe-NO bond. The large localization of unpaired spin density on the NO ligand is consistent with the observed I=1 hyperfine coupling in the g_2 region of the EPR spectrum (Figure 3). The other, out-of-plane NO π^* -based MOs (α -LUMO and β -LUMO+1) have compositions similar to the α -HOMO-1 and β -LUMO, though they are obviously derived from the other NO π^* orbital and are thus rotated by 90° about the N-O bond. For the NO adduct of Sec-Fe(II)CDO, the computed MO compositions and relative energies (data not shown) are very similar to those of the Cys-bound counterpart, consistent with the close correspondence between the Abs and EPR spectra exhibited by these two species.

To further validate these computed electronic structure descriptions and to assign the major features in the experimental Abs and MCD spectra, the electronic transition energies and Abs intensities were computed for the active sites of the OM/MM-optimized protein models. Initial attempts to use time-dependent density functional theory (TDDFT) to calculate the Abs spectra of the NO adducts of Cys- and Sec-bound Fe(II)CDO were unsuccessful, as the computed spectra contained a large number weak, low-energy features that have no experimental counterparts (see Figure S2). Therefore, subsequent electronic excited state computations were conducted on these active site models using the semi-empirical INDO/S-CI method; the relevant results obtained from these calculations are summarized in Figure 5. Overall, the agreement between the experimental and calculated Abs spectra is quite good, thus justifying a more detailed analysis of the INDO/S-CI results. Most of the transitions producing sizeable contributions to the computed spectrum are composed of numerous oneelectron excitations involving different donor and acceptor orbitals. Hence, the principal donor and acceptor orbitals for the transitions of interest were identified on the basis of electron density difference maps (see Figure 5, right). Visual inspection of these plots led to the Abs and MCD band assignments provided in Table 3.

A simultaneous Gaussian deconvolution of the Abs and MCD spectra of NO/Cys-Fe(II)CDO revealed that the major feature in the RT Abs spectrum at 24,600 cm⁻¹ is composed of two separate transitions (IV and V). In this same region, the INDO/S-CIpredicted spectrum shows two bands, whose individual transitions are labeled by iv, v_a, v_b, and v_c . Transition iv is predominantly an Fe $3d_{xz}\rightarrow NO$ π^* electronic excitation, while transitions v_a, v_b, and v_c all have significant contributions from excitations originating from the Fe $3d_{vz}$ and S 3p orbitals and terminating in the NO π^* orbital that is rotated by 90° about the N-O bond vector relative to the acceptor orbital for transition iv. The roughly orthogonal polarizations predicted for transitions iv and v are consistent with the appearance of a pseudo-A term associated with transition IV and V at ~ 24,500 cm⁻¹ in the experimental MCD spectrum. The Abs feature centered at 17,750 cm⁻¹ similarly contains contributions from two separate transitions (II and III). The energies and relative intensities of these transitions correlate well with the INDO/S-CI predicted transitions labeled ii and iii. The corresponding EDDMs show that these transitions possess predominantly S(Cys)/Fe $3d_{xz} \rightarrow NO \pi^* CT$ character. Finally, the lowest energy transition observed at 12,500 cm⁻¹ in the Abs spectrum (I) coincides with a range of transitions in the INDO-predicted spectrum. All of the predicted transitions in this region are Fe 3d→3d excitations. As this feature in the experimental Abs and MCD spectra could be fit with a single Gaussian band, transition I is assigned as the Fe $3d_{xz} \rightarrow 3d_{z}^2$ transition, which is predicted to carry the highest intensity in this region.

Because the computational package used for INDO/S-CI calculations lacks suitable parameters for selenium, we were unable to calculate an Abs spectrum for NO-bound Sec-Fe(II)CDO. Thus, to corroborate our band assignments on the basis of the shifts of the relevant electronic transitions caused by substituting Sec for Cys, the six transitions that dominate the Abs and MCD spectra of the NO/Cys-Fe(II)CDO species mentioned above were further analyzed. Since numerous one-electron excitations mix to result in a single predicted transition, visual inspection of the EDDMs was used us to identify the major oneelectron excitation responsible for each transition of interest for Cys/NO-bound Fe(II)CDO. As the MO compositions of the Cys/NO and Sec/NO adducts were very similar, the analogous one electron orbitals could readily be identified in the Sec/NO MO diagram. The energy differences were taken between the principal donor and acceptor MOs to compute pre-electronic relaxation transition energies for each of the two adducts, and the differences between these transitions energies are reported in Table 3. Although the absolute red-shifts are consistently underestimated, the transitions predicted to be the most affected by the substitution of Sec for Cys are indeed those displaying the largest red-shifts in the experimental Abs and MCD spectra. These red-shifts can be rationalized in terms of two mechanisms; namely, the decreased ligand field strength and the increased energies of the frontier MOs of Sec compared to Cys. Thus, the Fe $3d_{xz} \rightarrow 3d_z^2$ transition (I) is primarily affected by the stabilization of the Fe d_z2-based acceptor MO and the modest destabilization of the Fe 3d_{xz}-based donor MO upon substitution of Sec for Cys (note that the Fe 3d_{xz}-based orbital is weakly π -bonding with respect to the Fe-S/Se bond). Alternatively, the other transitions identified all contain substantial S/Se character in the donor MOs, so the higher frontier MO energies of Sec vs. Cys will also result in red-shifted transitions.

Discussion

Since the first crystal structure of CDO was published in 2006, ¹⁰ considerable interest in the catalytic mechanism of this enzyme, as well as in its overall contribution to oxidative cysteine metabolism, has been generated. The crucial developmental role this enzyme fills in mouse models ⁶⁰ and the epigenetic consequences of the *cdo1* gene promoter methylation ⁶¹ indicate that CDO plays a key part in the health of higher-order organisms. Work by Pierce and coworkers has demonstrated that an Fe(III)-superoxo species may be involved in the

overall mechanism,⁶² but beyond this no proposed catalytic intermediates have been experimentally observed. Through the detailed investigation of the electronic structure of a species closely mimicking a proposed enzyme intermediate (i.e., oxygen-bound Cys-Fe(II)CDO), we sought to shed light on the subsequent steps of the catalytic mechanism.

As stipulated by the EPR spectrum, our computational results indicate that the NO adducts of Cys- and Sec-Fe(II)CDO are best described as low-spin Fe(II) complexes possessing a single unpaired electron in an NO π^* -based MO. This electron configuration is very unusual for a {FeNO}⁷ non-heme iron enzyme species and is adopted by only a few synthetic {FeNO}⁷ complexes. ^{58, 59, 63} Several factors may contribute to the preference for the lowspin configuration by the NO adducts of CDO, including the unusual Fe(II) binding motif and the presence of a strongly electron-donating thiolate (or selenoate) ligand. However, the NO adduct of substrate-bound isopenicillin N-synthase, which features an iron-thiolate bonding interaction, adopts the more common S=3/2 ground state,⁵⁷ so the presence of the thiolate alone cannot account for the unusual spin state observed for CDO. Hence, it appears that both the 3His facial triad and a single, strongly donating anionic ligand are needed to stabilize the low-spin configuration. This hypothesis is supported by the fact that of the three known synthetic {FeNO}⁷ complexes that adopt an S=1/2 ground state, two have a mixed nitrogen- and oxygen-based, mono-anionic ligand set arranged in an octahedral geometry. 58, 59 While the third synthetic complex features two mono-anionic dithiolene ligands in addition to the nitrosyl ligand, its square-pyramidal ligand environment bears little resemblance to the CDO active site.⁶³

Precisely why S=1/2 rather than S=3/2 {FeNO}^7 adducts are formed upon the addition of NO to both Cys-bound and Sec-bound Fe(II)CDO remains unclear; however, some clues are provided by the computed MO diagrams for these species (Figure 4). Because S=3/2 {FeNO}^7 species can be described as containing a high-spin Fe(III) ion coupled antiferromagnetically to NO $^{-30}$ a hypothetical S=3/2 NO adduct of Cys-bound Fe(II)CDO would have all of its Fe 3d-based α spin MOs, as well as the in-plane and out-of-plane NO π^* -derived MOs in the β manifold, filled. In such a system, the population of the Fe 3d_x2_y2-based α MO (which has a substantial Fe-S(Cys) anti-bonding interaction) would result in a substantially weaker Fe-S bond than in the S=1/2 species. As such, these DFT results provide further support for our proposal that the strong Fe-S(Cys) bonding interaction is a major reason why NO/Cys-bound Fe(II)CDO adopts an S=1/2 ground state.

Extension to the Oxygen Adduct

Previous spectroscopic work has demonstrated the ability of Sec to bind to Fe(II)CDO in a manner similar to that of the native substrate Cys.²⁹ Here we have demonstrated that NO, a commonly utilized substrate analogue for O₂, can bind to both the Sec- and Cys-bound Fe(II)CDO active sites, yielding unusual S=1/2 {FeNO}⁷ species with virtually identical geometric and electronic structures. Despite these striking similarities, CDO is unable to oxidize Sec.²⁸ Hence, any proposed catalytic reaction mechanism for CDO must not only provide a reasonable route for the synthesis of cysteine sulfinic acid from Cys, but also account for the inability of CDO to oxidize Sec to its seleninic acid form.

In addition to providing electronic structure descriptions for the NO adducts of Cys- and Sec-bound Fe(II)CDO species that agree well with our spectroscopic data, our computations also properly predict similar driving forces for the formation of these species. Specifically, the energies of the nitrosyl adducts are within a few kcal/mol of the precursor energies, being +4.7 and -2.2 kcal/mol for the Cys- and Sec-bound species, respectively. These results are at least qualitatively consistent with our observation that not all available Fe(II)CDO active sites bind NO, as evidenced by the presence of the prominent features at >28,000 cm $^{-1}$ in the MCD spectra obtained at 4.5 K (where entropic effects not accounted

for in our calculations are negligible). Hence, the combined spectroscopic and computational investigation of these nitrosyl adducts has allowed us to validate a computational methodology that is suitable for predicting the geometric and electronic structures of catalytically relevant species. To this end, we replaced NO by O_2 in our computational models and investigated several viable reaction intermediates, including an end-on bound Fe- O_2 species ($\bf B$), one featuring a four-membered Fe- S_{Cys} -O-O ring ($\bf C$), and a post O-O bond scission species where the distal oxygen atom (O_d) has been transferred to the cysteinyl sulfur and the proximal oxygen atom (O_p) remains coordinated to the iron center ($\bf D$). In each case, several spin states were investigated (see Figure 6 and Table 4). Because the main goal of these calculations was to obtain clues as to why Fe(II)CDO is unable to convert Sec to its seleninic acid form, entropic effects that should similarly affect the free energies of the Cys- and Sec-bound intermediates were not accounted for.

A summary of the proposed electronic structures for the lowest energy intermediates along the Cys reaction pathway are shown in Scheme 1, while relevant MO diagrams and Loewdin spin densities are provided in Figures S3–S6 in the Supporting Information. An examination of the initial O₂- and Cys-bound Fe(II)CDO intermediate (**B**) reveals that the quintet spin state (in which an intermediate spin S=3/2 Fe(III) is formally coupled ferromagnetically to a superoxide radical) is stabilized by ≈ 9 kcal/mol with respect to the Cys-bound Fe(II)CDO species and free O_2 (A). The ${}^3\mathbf{B}$ and ${}^1\mathbf{B}$ species are predicted to be less stable than the ${}^5\mathbf{B}$ species by 24 kcal/mol and 36 kcal/mol, respectively. In the S=2 species, the Fe center adopts a distorted octahedral geometry, with a His₈₈-Fe-O_p bond angle of 163.8°. The unpaired electron on the O₂⁻⁻ moiety is located in an MO that is oriented perpendicular to the Fe-O-O plane. It is worth noting that the {FeNO}⁷ adduct discussed earlier was assigned to be a low-spin Fe(II) with an NO, whereas the O₂-adduct is proposed to have an intermediate spin Fe(III). Nitric oxide is a relatively weak oxidant [E° (NO/ 3 NO⁻) = -0.8 V vs. NHE⁶⁴], whereas O₂ has a much greater oxidizing power [E° (O₂/O₂⁻) = -0.16 V vs. NHE⁶⁵]. With this in mind, it is perhaps not surprising why our computations predict that dioxygen can oxidize the Fe center of CDO, while NO lacks this ability.

The next intermediate is formally obtained through the attack of the cysteinyl sulfur's lone pair on O_d and subsequent electron transfer from superoxide back to the Fe(III) center. For this intermediate (C), the quintet spin state is again lowest in energy. This species is best described as possessing a high-spin S=2 Fe(II) ion bound to a persulfenate moiety. A spin-crossover event to an S=1 state is predicted to occur upon moving from this intermediate via homolytic cleavage of the O_p - O_d bond to the singly oxygenated sulfur intermediate (${}^3\mathbf{D}$). Based on the MO energies and compositions, this complex can be described as a resonance hybrid between an intermediate-spin Fe(III) bound to O^- (major contributor) and an Fe(IV)-oxo-like species. Unpaired β electrons are localized on both the sulfur and the distal oxygen, and the coupling of these to the α electrons on Fe(III) and O_p results in the S=1 state. Although the next step of the reaction was not investigated computationally in this work, it is likely that the α electron on O_p and the β electron on the sulfur can recombine to form the final S-O bond. The homolytic cleavage of the Fe- O_p bond would then result in a one-electron-reduced iron center, yielding an Fe(II)-product complex.

The Cys-related catalytic intermediates A–D proposed in this work seem plausible, with all intermediates investigated having at least one low-energy spin state that should be accessible. Additionally, the geometries and energies of the analogous Sec-bound intermediates provide clues as to why Sec is not oxidized by CDO. Whereas the S=2 oxygen adduct of Cys-bound Fe(II)CDO (5B) is stabilized with respect to its precursor and free 3O_2 , the analogous S=2 oxygen adduct of Sec-bound Fe(II)CDO (species $^5B'$) is much higher in energy and is no longer the ground state O_2 -bound species (that being $^3B'$). This energetic difference is likely a direct result of the fact that the geometries of 5B and $^5B'$ are

considerably different (see Figure 7). Rather than binding in an end-on fashion to the Fe(II) center as in 5B , the dioxygen moiety in ${}^5B'$ has shifted to insert above the Fe-Se bond instead, in a manner nearly identical to what is observed in the crystal structure of persulfenate-bound CDO (PDB file 3ELN). 43 The 3ELN crystal structure was proposed to be that of a reaction intermediate of the oxidation of Cys, though the crystals from which the structure was obtained were soaked with Cys in an aerobic atmosphere for a period of 1–4 hours before diffraction data were collected, thus having ample time for an on-pathway intermediate to completely turn over. 43 Having obtained a similar structure through the *in silico* reaction of Sec-Fe(II)CDO with O_2 , it seems plausible that the persulfenate-CDO complex is not a relevant reaction intermediate, but rather represents an off-reaction-pathway species. In the case of Sec-bound Fe(II)CDO, the high energy of the ${}^5B'$ species suggests that the formation of a dioxygen adduct is thermodynamically unfavorable. This hypothesis is consistent with our observation that CDO samples prepared anaerobically in the presence of Sec are spectroscopically indistinguishable from those prepared aerobically.

Two purely computational investigations into the mechanism of CDO have recently been reported in the literature, including a QM/MM study performed by Kumar et al. that employed a slightly different computational methodology from that used in our work.²⁶ For the four-membered ring and post-O₂ bond scission intermediates (C and D, respectively), the energetic ordering of the spin states, as well as the relative energies between them, are very similar to ours. However, large differences exist regarding the identity of the initial O₂bound intermediate. While we favor an S=2, pseudo-octahedral complex (⁵B in Figure 6), the corresponding species in the Kumar study has a nearly perfect octahedral geometry about the Fe center and is much higher in energy than both the S=0 (most stable) and S=1 species. The main difference between our ⁵B model and the S=0 species reported by Kumar et al concerns the relative energy of the Fe 3d₂2 orbital. In the former species this orbital is sufficiently low in energy to become singly occupied, while in the latter it remains unoccupied. However, it is worth noting that the choice of functional and computational methodology utilized in calculations such as those presented here may have a profound effect on the predicted energetic ordering of spin states. ⁶⁶ Keeping this in mind, we are cautiously optimistic that our computational methodology, which was validated on the basis of the experimental Abs and MCD spectra of the NO adducts of Cys- and Sec-bound Fe(II)CDO, is capable of providing molecular orbitals, energies, and compositions that are consistent with those found in this enzyme system.

A second, more recent computational investigation by Che, et al. also evaluated a possible mechanism for CDO. 67 In this case, only the enzyme's first coordination sphere was considered. Thus, all outer-sphere contributions to the energy, geometry, and electronic structure of the active site were ignored. Che's study investigated the substitution of Cys for Sec, and it was proposed that the enzyme is incapable of oxidizing Sec because a ferric-superoxo complex is never formed. This was attributed to selenium's superior electron donation ability, which resulted in no change in oxidation state at the iron center upon O_2 binding. However, Che proposes that O_2 is still capable of binding to Sec-bound Fe(II)CDO to yield a high-spin Fe(II) ion coupled ferromagnetically to a superoxo radical and coupled antiferromagnetically to a selenium-based radical. This conclusion is inconsistent with our observation that the active site is unreactive to O_2 if Sec is already bound to the iron center.

Conclusions

The uncommon S=1/2 {FeNO}⁷ species generated upon the reaction of NO with a preformed Cys-Fe(II)CDO or Sec-Fe(II)CDO complex represents yet another unusual characteristic of the CDO enzyme. This adduct presented us with an almost unique opportunity to explore the spectral signatures and electronic properties of unusual S=1/2

 $\{\text{FeNO}\}^7$ species. Through the validation of our computational methodology via the successful prediction of the geometric and electronic structures of these nitrosyl adducts, we were able to investigate the geometries and energetics associated with several proposed reaction intermediates. In doing so, it was discovered that the Cys-bound active site has a low-lying S=2 intermediate after O₂ binding that is inaccessible to the Sec-bound active site, providing a possible explanation for the lack of reactivity of Sec-Fe(II)CDO toward O₂.

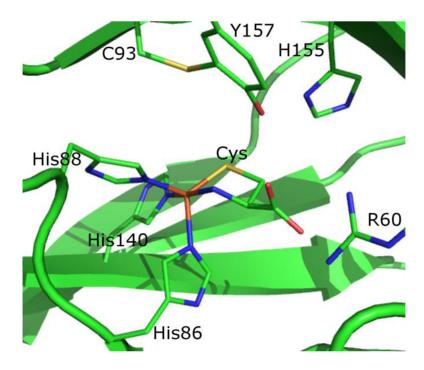

Figure 1. Crystal structure of human CDO with substrate Cys bound to the iron center. ¹¹ The putative O₂ (or NO) binding site is located trans to His86.

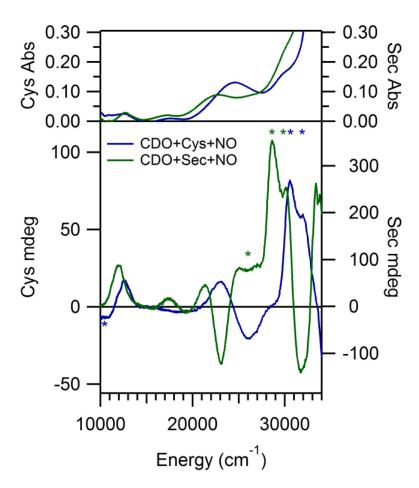

Figure 2.Room temperature Abs (top) and 4.5 K MCD (bottom) spectra of Cys-Fe(II)CDO and Sec-Fe(II)CDO after exposure to NO(g). Features present due to unreacted Sec- or Cys-Fe(II)CDO or glass strain are marked by *.

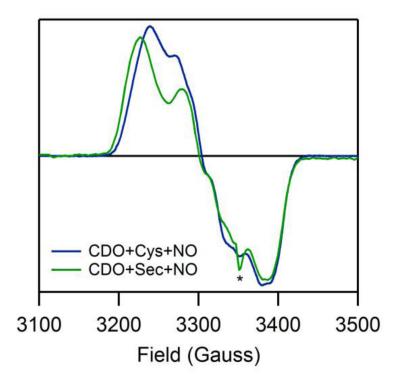

Figure 3. 20 K EPR spectra of NO/Cys-Fe(II)CDO and NO/Sec-Fe(II)CDO. Note that a minor underlying signal attributed to the *in situ* formation of a dinitrosyl iron complex is also present (*).

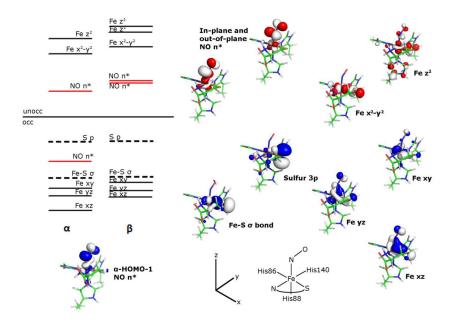

Figure 4. MO energy level diagram obtained from a single-point DFT calculation on the QM/MM-optimized active site model of the nitrosyl adduct of Cys-Fe(II)CDO. Boundary surface plots of the α -HOMO-1 (bottom left) and relevant β orbitals (right) are also shown. Note that the HOMO-LUMO energy gap is not to scale.

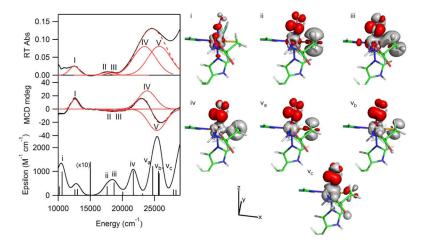

Figure 5.Gaussian deconvolutions and band labels for the low energy regions of the RT Abs and 4.5 K MCD spectra with the results of the INDO/S-CI calculation for comparison. Also shown are the EDDMs plotted for the transitions of interest (red and gray represent gain and loss of electron density, respectively). The model is oriented in a similar fashion as in Figure 4.

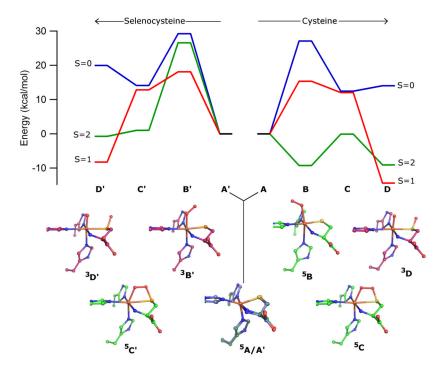

Figure 6. Calculated reaction coordinate diagrams and active site models of QM/MM-optimized reaction intermediates for the oxidation of Cys ($\mathbf{A} \rightarrow \mathbf{D}$) and Sec ($\mathbf{A}' \rightarrow \mathbf{D}'$) by Fe(II)CDO. All energies are given relative to those of high-spin Cys- or Sec-Fe(II)CDO plus free 3O_2 . In both the energy diagram and the active site overlays, the S=0, 1, and 2 species are shown in blue, red, and green, respectively, except $^5\mathbf{A}$ and $^5\mathbf{A}'$, whose models are shown in dark blue and dark green, respectively. For clarity, only the first coordination sphere has been shown, and all hydrogen atoms have been omitted.

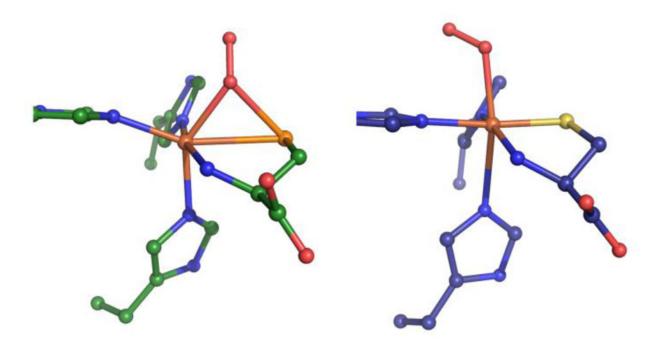

Figure 7.

Comparison of the QM/MM-optimized structures for ⁵B' (left) and ⁵B (right).

Scheme 1.

Formal electronic configurations of the proposed lowest energy reaction intermediates along the Cys reaction pathway. Electrons originating from the S(Cys) lone pair are shown in gray, and only relevant atoms are shown for clarity.

Blaesi et al.
